

# Midterm 1, Fall 2021: Chess Ratings

Version 1.0

Change Log: 1.0 - Initial Release

This problem builds on your knowledge of **Python data structures, string processing, and implementing mathematical functions**.

For other preliminaries and pointers, refer back to the Piazza post titled **"Midterm 1 Release Notes"**.

- Total Exercises: **8**
- Total Points: **16**
- Time Limit: **3 Hours**

Each exercise builds logically on the previous one, but you may **solve them in any order**. That is, if you can't solve an exercise, you can still move on to the next one. **However, if you see a code cell introduced by the phrase, "Sample result for ...", please run it.** Some demo cells in the notebook depend on these precomputed results.

The point values of individual exercises are as follows:

- Exercise 0: 3 points
- Exercise 1: 2 points
- Exercise 2: 1 points
- Exercise 3: 2 points
- Exercise 4: 1 points
- Exercise 5: 3 points
- Exercise 6: 2 points
- Exercise 7: 2 points

**Good luck!**

## Elo Ratings

The Elo (rhymes with "Hello") rating system is a widely used method for quantifying relative skill levels of players in a game or sport. The method is used to rate chess players and is named for its creator, Arpad Elo. This system is very simple but is able to rate players much more effectively than a win-loss record.

On a high level, the winning player in a game takes rating points away from the losing player. How many points change hands is determined by the difference in the initial ratings of each player. For example, if a highly rated player records a victory over a lower rated player, then they would gain only a few points, which is reflective of the highly rated player being expected to win. However, if the lower rated player is able to pull off an upset, a larger quantity of points would be exchanged. The idea is that over time the system will adjust players' ratings to their true relative skill levels. Additionally, the difference in Elo ratings between two players can be used to calculate the expectation for the number of wins each player would accrue, which is often expressed as "win probability".

Here we will extract data from a recent chess tournament that captures players' ratings at the start of the tournament and the outcome of all games. We will then use that data to calculate expected wins based on the matchups and compare our expectation with the observed results. Finally we will calculate the updated Elo ratings for the players. There are many variations on this system, but here we will use the original version. You can find more information about the Elo rating system [here](https://en.wikipedia.org/wiki/Elo_rating_system) ([https://en.wikipedia.org/wiki/Elo\\_rating\\_system](https://en.wikipedia.org/wiki/Elo_rating_system)).

Let's get started by taking a look at the data!

```
In [1]: ###
      ### AUTOGRADER TEST - DO NOT REMOVE
      ###

      import run_tests as test_utils
      raw_data = test_utils.read_raw_data('Bucharest2021.pgn')
      test_utils.get_mem_usage_str()
```

```
Out[1]: '47.8 MiB'
```

Take note of how the data is **split** into sections by **blank lines** ('`\n\n`'); this fact might be useful later on! (*hint! hint!*) Here are the first 4 sections of the data:

```
In [2]: demo_raw_data = '\n\n'.join(raw_data.split('\n\n')[:4])
      print(demo_raw_data)

      [Event "Superbet Classic 2021"]
      [Site "Bucharest ROU"]
      [Date "2021.06.05"]
      [Round "1.5"]
      [White "Deac,Bogdan-Daniel"]
      [Black "Giri,A"]
      [Result "1/2-1/2"]
      [WhiteElo "2627"]
      [BlackElo "2780"]
```

```
'result': '1/2-1/2',
'white_rating': 2656,
'black_rating': 2781}]
```

To help you get started, consider the following snippet, which converts `demo_raw_data` into a nested list of lists. A similar strategy may be helpful for the `raw_data` parameter in the exercise.

```
In [3]: demo_metadata_list = [metadata.splitlines() for metadata in demo_raw_data.split('\n\n')[::2]]
print(f'type(demo_metadata_list[0]): {type(demo_metadata_list[0])}') # outer list items are lists
print(f'type(demo_metadata_list[0][0]): {type(demo_metadata_list[0][0])}') # inner list items are strings
demo_metadata_list
```

```
type(demo_metadata_list[0]): <class 'list'>
type(demo_metadata_list[0][0]): <class 'str'>
```

```
Out[3]: [['[Event "Superbet Classic 2021"]',
 '[Site "Bucharest ROU"]',
 '[Date "2021.06.05"]',
 '[Round "1.5"]',
 '[White "Deac,Bogdan-Daniel"]',
 '[Black "Giri,A"]',
 '[Result "1/2-1/2"]',
 '[WhiteElo "2627"]',
 '[BlackElo "2780"]',
 '[ECO "D43"]'],
 '[Event "Superbet Classic 2021"]',
 '[Site "Bucharest ROU"]',
 '[Date "2021.06.05"]',
 '[Round "1.4"]',
 '[White "Lupulescu,C"]',
 '[Black "Aronian,L"]',
 '[Result "1/2-1/2"]',
 '[WhiteElo "2656"]',
 '[BlackElo "2781"]',
 '[ECO "E39"]']]
```

```
In [101]: def extract_games(raw_data):

g': 2656, 'black_rating': 2781}]

```

Out[16]: '48.9 MiB'

## Exercise 1 (2 points)

The next bit of information we will need in our analysis is the outcome of each player's games paired with their opponent.

Fill out the function `extract_player_results(games)` in the code cell below with the following requirements:

Given `games`, a list of dictionaries containing the metadata for each game, create dictionary `player_results` mapping each player's name to a list of outcomes of that player's games. Each outcome should include the opponent's name (String) and the number of points that the player received outcome of the game as a Tuple.

The order of tuples in the list associated with each player should be the **same as the order of the matchups in games**.

You should interpret the value associated with 'result' as "<white player points>-<black player points>" separated by a dash "-". The possible outcomes of a game of chess: White wins ('1-0'), black wins ('0-1'), or draw ('1/2-1/2').

For example, if the input is:

```

[{'white_player': 'Dwight Schrute', 'black_player': 'Jim Halpert', 'result': '1-0'}, {'white_player': 'Stanley Hudson',
'black_player': 'Dwight Schrute', 'result': '1/2-1/2'}]

```

Then the output should be:

```

{'Dwight Schrute': [('Jim Halpert', 1.0), ('Stanley Hudson', 0.5)], 'Jim Halpert': [('Dwight Schrute', 0.0)], 'Stanley Hudson':
[('Dwight Schrute', 0.5)]}

```

You can assume that each dictionary in `games` will have the keys 'white\_player', 'black\_player', and 'result' and that the values associated with those keys are Strings. There may be duplicated matchups where the same two players are paired in the tournament more than once. These should be handled the same as any other game and do not require any special treatment.

```

In [17]: demo_games_metadata = [{'white_player': 'Dwight Schrute', 'black_player': 'Jim Halpert', 'result': '1-0'},
{'white_player': 'Stanley Hudson', 'black_player': 'Dwight Schrute', 'result': '1/2-1/2'}]

```

```

In [20]: def extract_player_results(games):
        ###
        ### YOUR CODE HERE
        ###
        from collections import defaultdict
        results = defaultdict(list)
        for game in games:
            white = game['white_player']
            black = game['black_player']
            white_pts = 1.0 if game['result'] == '1-0' else 0.0 if game['result'] == '0-1' else 0.5
            black_pts = 1.0 if game['result'] == '0-1' else 0.0 if game['result'] == '1-0' else 0.5

```

```

        results[white].append((black, white_pts))
        results[black].append((white, black_pts))
    return results
# Demo
extract_player_results(demo_games_metadata)

```

```

Out[20]: defaultdict(list,
      {'Dwight Schrute': [('Jim Halpert', 1.0), ('Stanley Hudson', 0.5)],
      'Jim Halpert': [('Dwight Schrute', 0.0)],
      'Stanley Hudson': [('Dwight Schrute', 0.5)]})

```

```

Passed!

```

Out[21]: '48.9 MiB'

```

### Run the following cell, even if you skipped Exercise 1.

We are loading a pre-computed solution that will be used in the following sections. The first two entries are displayed.

```

In [22]: # Sample result for ex1
player_results = test_utils.read_pickle('player_results')
{k:v for k, v in list(player_results.items())[:2]}

```

```

Out[22]: {'Deac,Bogdan-Daniel': [('Giri,A', 0.5),
      ('Vachier', 1.0),
      ('Mamedyarov,S', 0.5),
      ('Grischuk,A', 0.0),
      ('So,W', 0.5),
      ('Radjabov,T', 0.5),
      ('Lupulescu,C', 0.5),
      ('Aronian,L', 0.0),
      ('Caruana,F', 0.5)],
      'Giri,A': [('Deac,Bogdan-Daniel', 0.5),
      ('Radjabov,T', 0.5),
      ('Lupulescu,C', 0.0),
      ('Aronian,L', 0.5),
      ('Caruana,F', 0.5),
      ('So,W', 0.5),
      ('Vachier', 1.0),
      ('Grischuk,A', 0.5)]}

```

## Exercise 2 (1 point)

Our next task is to compute the total tournament score for each player.

Fill in the function `calculate_score(player_results)` satisfying the following requirements:

Given a dictionary `player_results` mapping player names to their tournament results (similar to the output of Exercise 1), create a **new** dictionary `player_scores` that maps each player (String) to their total score for the tournament (Float).

For example, given the following input:

```

{'Angela Martin': [('Oscar Martinez', 1.0), ('Kevin Malone', 0.5), ('Andy Bernard', 0.0)], 'Michael Scott': [('Pam Halpert', 0.0), ('Toby Flenderson', 0.0), ('Todd Packer', 0.0)]}

```

Your function should output:

```

{'Angela Martin': 1.5, 'Michael Scott': 0.0}

```

(Michael isn't exactly a chess prodigy...)

You can assume that the lists keyed to each String in the input will be of the form (String, Float). You do not need to worry about verifying that all implied by the input are present. If you look closely at the example, you will see that this is **not** the case.

```

In [23]: demo_player_results = {'Angela Martin': [('Oscar Martinez', 1.0), ('Kevin Malone', 0.5), ('Andy Bernard', 0.0)],
      'Michael Scott': [('Pam Halpert', 0.0), ('Toby Flenderson', 0.0), ('Todd Packer', 0.0)]}

```

```

In [84]: def calculate_score(player_results):
      ###

```

```

### YOUR CODE HERE
###
from collections import defaultdict
scores = defaultdict(float)
for player, results in player_results.items():
    for result in results:
        scores[player] += result[1]
return scores
def calculate_score(player_results):
    ###
    ### YOUR CODE HERE
    ###
    return {player: sum(pts for _, pts in results) for player, results in player_results.items()}
# Demo
calculate_score(demo_player_results)

```

Out[84]: {'Angela Martin': 1.5, 'Dwight Schrute': 0.5}

The test cell below runs your function **many times**. Remove or comment out any print statements to avoid generating excessive output.

```

In [85]: # `ex2_test`: Test cell
from run_tests import ex2_test
for _ in range(200):
    ex2_test(10, 4, calculate_score)
print('Passed!')

###
### AUTOGRADER TEST - DO NOT REMOVE
###
test_utils.get_mem_usage_str()

```

Passed!

Out[85]: '88.1 MiB'

**Run the following cell, even if you skipped Exercise 2.**

We are loading a pre-computed solution that will be used in the following sections. The first two entries are displayed.

```

In [30]: # Sample result for ex2
player_scores = test_utils.read_pickle('player_scores')
{k:v for k, v in list(player_scores.items())[:2]}

```

Out[30]: {'Deac,Bogdan-Daniel': 4.0, 'Giri,A': 4.0}

## Exercise 3 (2 points)

Our next task is to extract the Elo rating of each player from the metadata.

Fill in the function `extract_ratings(games)` to satisfy the following requirements:

Given a list of dictionaries, `games`, create a dictionary `player_ratings` that maps each player to their Elo rating before the tournament. You can assume each dictionary in `games` will have the following keys and value types: `'white_player': (String)`, `'black_player': (String)`, `'white_rating': (Integer)`, `'black_rating': (Integer)`.

Additionally, if the same player has different ratings in the input, your function should raise a `ValueError`.

For example:

Input: `[{'white_player': 'Jim Halpert', 'black_player': 'Darryl Philbin', 'white_rating': 1600, 'black_rating': 1800}, {'white_player': 'Darryl Philbin', 'black_player': 'Phyllis Vance', 'white_rating': 1800, 'black_rating': 1700}]`

Output: `{'Darryl Philbin': 1800, 'Jim Halpert': 1600, 'Phyllis Vance': 1700}`

Input: `[{'white_player': 'Jim Halpert', 'black_player': 'Darryl Philbin', 'white_rating': 1600, 'black_rating': 1800}, {'white_player': 'Darryl Philbin', 'black_player': 'Phyllis Vance', 'white_rating': 1850, 'black_rating': 1700}]`

Here 'Darryl Philbin' has two ratings: 1800 in his first game and 1850 in his second. Your function should raise a `ValueError`!

```

In [32]: demo_metadata_good = [{'white_player': 'Jim Halpert', 'black_player': 'Darryl Philbin', 'white_rating': 1600, 'black_rating': 1800}, {'white_player': 'Darryl Philbin', 'black_player': 'Phyllis Vance', 'white_rating': 1800, 'black_rating': 1700}]
demo_metadata_bad = [{'white_player': 'Jim Halpert', 'black_player': 'Darryl Philbin', 'white_rating': 1600, 'black_rating': 1800}, {'white_player': 'Darryl Philbin', 'black_player': 'Phyllis Vance', 'white_rating': 1850, 'black_rating': 1700}]

```

```

In [33]: def extract_ratings(games):
    ###
    ### YOUR CODE HERE
    ###
    from collections import defaultdict
    rating_sets = defaultdict(set)

```

```

    ~
    for game in games:
        white = game['white_player']
        black = game['black_player']
        w_rating = game['white_rating']
        b_rating = game['black_rating']
        rating_sets[white].add(w_rating)
        rating_sets[black].add(b_rating)
    ratings = {}
    for player, rs in rating_sets.items():
        if len(rs) != 1: raise ValueError
        ratings[player] = list(rs)[0]
    return ratings
# Demo
try:
    extract_ratings(demo_metadata_bad)
    print('This should raise a ValueError')
except ValueError:
    print('Correctly raised ValueError')
extract_ratings(demo_metadata_good)
```

Correctly raised ValueError

Out[33]: {'Jim Halpert': 1600, 'Darryl Philbin': 1800, 'Phyllis Vance': 1700}

The test cell below runs your function **many times**. Remove or comment out any print statements to avoid generating excessive output.

```

In [34]: # `ex3_test`: Test cell
from run_tests import ex3_test
for _ in range(200):
    ex3_test(10, 4, extract_ratings)
print('Passed!')

###
### AUTOGRADER TEST - DO NOT REMOVE
###
```

Passed!

Run the following cell, even if you skipped Exercise 3.

We are loading a pre-computed solution that will be used in the following sections. The first two entries are displayed.

```

In [35]: # Sample result for ex3
player_ratings = test_utils.read_pickle('player_ratings')
{k:v for k, v in list(player_ratings.items())[:2]}
```

Out[35]: {'Deac,Bogdan-Daniel': 2627, 'Giri,A': 2780}

## Exercise 4 (1 point)

The last task before we begin analysis is to implement some functionality to calculate the expected result of a match based on the Elo ratings of

Fill out the function `expected_match_score(r_player, r_opponent)` to satisfy the following requirements:

Given a player's rating (Integer) and their opponent's rating (Integer), compute the player's expected score in a game against that opponent. The the expected score is:

$$\text{Expected Score} = \frac{1}{1 + 10^d}$$

where

$$d = \frac{r_{\text{opponent}} - r_{\text{player}}}{400}$$

Output the expected score as a Float. **Do not round**.

For example:

`expected_match_score(1900, 1500)` should return about 0.909

`expected_match_score(1500, 1500)` should return about 0.5

`expected_match_score(1900, 1700)` should return about 0.76

```

In [37]: demo_ratings = [(1900, 1500), (1500, 1500), (1900, 1700)]
```

```

In [38]: def expected_match_score(r_player, r_opponent):
    ###
    ### YOUR CODE HERE
    ###
    d = (r_opponent - r_player)/400
    return 1 / (1 + 10 ** d)
# Demo
for rp, ro in demo_ratings:
    print(f'expected match score({rp}, {ro}) = {expected_match_score(rp, ro)}')
```

```
print('expected_match_score(1500, 1500) =', expected_match_score(1500, 1500))
```

```
expected_match_score(1900, 1500) = 0.9090909090909091
expected_match_score(1500, 1500) = 0.5
expected_match_score(1900, 1700) = 0.7597469266479578
```

The test cell below runs your function **many times**. Remove or comment out any print statements to avoid generating excessive output.

```
In [39]: # `ex4_test`: Test cell
#####
##### AUTOGRADER TEST - DO NOT REMOVE
#####
from run_tests import ex4_test
for _ in range(200):
    ex4_test(expected_match_score)
print('Passed!')

#####
##### AUTOGRADER TEST - DO NOT REMOVE
#####
test_utils.get_mem_usage_str()
```

Passed!

Out[39]: '49.1 MiB'

## Aside - Functional Programming

It is often useful to write functions which take other functions as arguments. Inside of your function, the functional argument is called in a consistent way that allows the caller of your function to customize its behavior.

Here is an over-engineered arithmetic calculator as an example. These functions define mathematical operations.

```
In [40]: # add
def a(a, b):
    return a+b
# subtract
def s(a, b):
    return a-b
# multiply
def m(a, b):
    return a*b
# divide
def d(a,b):
    return a/b
```

This function, `calc`, takes the two numbers as an argument and a third argument which determines how they are combined.

```
In [41]: def calc(a, b, opp):
        return opp(a,b)
```

Now we can use any function that takes two arguments, like the 4 defined above to determine the behavior of `calc`.

```
In [42]: calc(3,5,a)
```

Out[42]: 8

```
In [43]: calc(3,5,d)
```

Out[43]: 0.6

## Exercise 5 (3 points)

Our next task is to write some functionality to determine each player's expected tournament score.

Fill in the function `expected_tournament_score(player_results, player_ratings, es_func)` to satisfy the following requirements:

Given a dictionary, `player_results`, mapping players to their tournament results as a list of tuples (similar to the output from Exercise 1) and a `player_ratings`, mapping players to their Elo ratings, compute the **total** expected score for each player (you only need to compute total expected scores for players that are keys in `player_results`). The total expected score is simply the sum of the expected scores for each of that player's games. Output results as a dictionary mapping players (String) to their expected tournament score (Float).

The third argument `es_func` is a function that takes two arguments (the player's rating and opponent's rating respectively) and returns an "expected score". You should use it to compute the expected scores for this exercise. **It might not be the same as the solution to Exercise 4!**

A call to `es_func(1450, 1575)` inside of your function would compute the "expected score" for the 1450-rated player against a 1575-rated player.

For example given:

```
player_results = {'Angela Martin': [('Dwight Schrute', 1.0), ('Stanley Hudson', 0.5)], 'Dwight Schrute': [('Angela Martin', 0.0), ('Jim Halpert', 0.5)]}
```

```
player_ratings = {'Angela Martin': 1600, 'Dwight Schrute': 1750, 'Stanley Hudson': 1800, 'Jim Halpert': 1700}
```

```
es_func = lambda r_player, r_opponent: float(r_player - r_opponent)
```

The output would be:

```
{'Angela Martin': -350.0, 'Dwight Schrute': 200.0}
```

```
In [88]: demo_player_results = {'Angela Martin': [('Dwight Schrute', 1.0), ('Stanley Hudson', 0.5)], 'Dwight Schrute': [('Angela Martin', 0.0), ('Jim Halpert', 0.5)]}
demo_player_ratings = {'Angela Martin': 1600, 'Dwight Schrute': 1750, 'Stanley Hudson': 1800, 'Jim Halpert': 1700}
demo_es_func = lambda r_player, r_opponent: float(r_player - r_opponent)
```

```

```

```
Out[94]: {'Angela Martin': -350.0, 'Dwight Schrute': 200.0}
```

The test cell below runs your function **many times**. Remove or comment out any print statements to avoid generating excessive output.

```
In [95]: # `ex5_test`: Test cell
from run_tests import ex5_test
for _ in range(200):
    ex5_test(10, 4, expected_tournament_score)
print('Passed!')

"""
"""
""" AUTOGRADER TEST - DO NOT REMOVE """
"""
test_utils.get_mem_usage_str()
```

Passed!

```
Out[95]: '88.1 MiB'
```

**Run the following cell, even if you skipped Exercise 5.**

We are loading a pre-computed solution that will be used in the following sections. The first two entries are displayed.

```
In [96]: # Sample result for ex5
player_expected_score = test_utils.read_pickle('player_expected_score')
{k:v for k, v in list(player_expected_score.items())[:2]}
```

```
Out[96]: {'Deac,Bogdan-Daniel': 2.827559638896802, 'Giri,A': 4.389932419673484}
```

## Exercise 6 (2 points)

Fill in the function `compute_final_ratings(player_scores, expected_player_scores, player_ratings)` to meet the following requirements.

Given three dictionaries:

- `player_scores`: mapping players (String) to their observed tournament scores (Float)
- `expected_player_scores`: mapping players (String) to their expected tournament scores (Float)
- `player_ratings`: mapping players (String) to their pre-tournament Elo ratings (Float)

calculate each player's post-tournament Elo ratings using this formula:

$$\text{Rating}_{\text{post}} = \text{Rating}_{\text{pre}} + 10(\text{Score}_{\text{observed}} - \text{Score}_{\text{expected}})$$

Return a dictionary mapping each player (String) to their post-tournament rating **rounded to the nearest integer**.

For example:

old\_ratings = {'Ryan Howard': 1755, 'Dwight Schrute': 1675}

new\_ratings = {'Michael Scott': 1250, 'Ryan Howard': 1750}

Should return:

{'Michael Scott': 50, 'Ryan Howard': -5, 'Dwight Schrute': 0}

```
In [55]: demo_old_ratings = {'Ryan Howard': 1755, 'Dwight Schrute': 1675}
demo_new_ratings = {'Michael Scott': 1250, 'Ryan Howard': 1750}
```

```
In [56]: def compute_deltas(old_ratings, new_ratings):
    """
    """
    """ YOUR CODE HERE """
    """
    both = set(old_ratings.keys()) & set(new_ratings.keys())
    old = set(old_ratings.keys()) - set(new_ratings.keys())
    new = set(new_ratings.keys()) - set(old_ratings.keys())
    deltas = {}
    for player in both:
        deltas[player] = new_ratings[player] - old_ratings[player]
    for player in new:
        deltas[player] = new_ratings[player] - 1200
    for player in old:
        deltas[player] = 0
    return deltas
# Demo
compute_deltas(demo_old_ratings, demo_new_ratings)
```

```
Out[56]: {'Ryan Howard': -5, 'Michael Scott': 50, 'Dwight Schrute': 0}
```

The test cell below runs your function **many times**. Remove or comment out any print statements to avoid generating excessive output.

```
In [57]: # `ex7_test`: Test cell
from run_tests import ex7_test
for _ in range(200):
    ex7_test(10, compute_deltas)
print('Passed!')

"""
"""
""" AUTOGRADER TEST - DO NOT REMOVE """
"""
test_utils.get_mem_usage_str()
```

Passed!

```
Out[57]: '49.1 MiB'
```

## Wrapping up

After parsing all of the information from the text file, we can display a summary of the tournament results.

```
In [58]: import pandas as pd
df = pd.DataFrame(index=player_scores.keys())
df['Initial Rating'] = pd.Series(player_ratings)
df['Score'] = pd.Series(player_scores)
df['Expected Score'] = pd.Series(player_expected_score)
df['Final Rating'] = pd.Series(player_final_ratings)
df['Delta'] = pd.Series(test_utils.read_pickle('player_deltas'))
display(df)
```

	Initial Rating	Score	Expected Score	Final Rating	Delta
Deac,Bogdan-Daniel	2627	4.0	2.827560	2639	12
